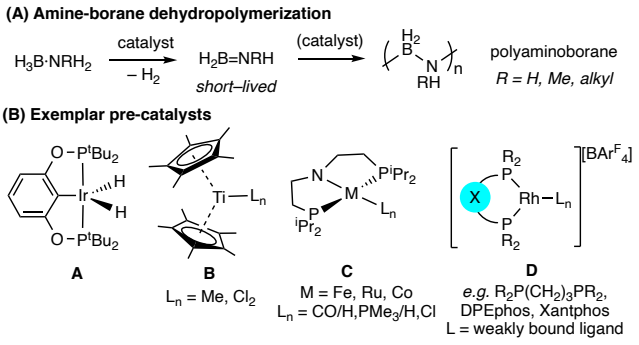
Keywords: Dehydropolymerization, Rhodium, Phosphine, Mechanism, Amine-borane

A detailed study of $H_3B{\cdot}NMeH_2$ dehydropolymerization using the cationic pre-catalyst $[Rh(DPEphos)(H_2BNMe_3CH_2CH_2{}^tBu)][BAr^F{}_4]$, identifies the resting state as dimeric $[Rh(DPEphos)H_2]_2$ and boronium $[H_2B(NMeH_2)_2]^+$ as the chain-control agent. $[Rh(DPEphos)H_2]_2$ is conveniently generated in situ from Rh(DPEphos)(benzyl), and catalyzes polyaminoborane formation, M_n = 15000 g mol^{-1}]. Closely-related Rh(Xantphos)(benzyl) operates on gram scale, at 0.1 mol%, to afford higher molecular weight polymer [M_n = 85000 g mol^{-1}] with low residual [Rh], 81 ppm. This insight offers a mechanistic template for dehydropolymerization.

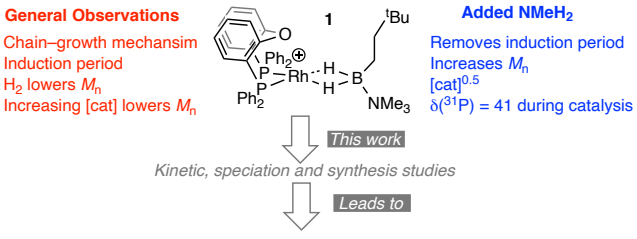
The catalyzed dehydropolymerization of amine-boranes, archetypically $H_3B{\cdot}NMeH_2$, is an atom-efficient methodology for the synthesis of polyaminoboranes $(H_2BNRH)_n$ (Scheme 1A), forming H_2 as the only by-product.[1-4] This new class of main-group polymer[5] is based upon BN main-chain units, and is isosteric with technologically-mature polyolefins. These main-chain B–N units suggest, in addition to unexplored material and chemical properties, potential applications as piezoelectric materials,[6,7] or as precursors to boron-based ceramics and *h*-BN.[1,8,9] The currently accepted overarching mechanism for polymer formation from amine-borane involves initial dehydrogenation to form a transient[10] aminoborane ($H_2B{=}NRH$), that then undergoes end-chain nucleophilic B–N bond formation, initiated by the catalyst.[3,11-16] While non-catalytic routes have been reported,[10,17] in terms of overall efficiency, scalability, substrate scope, and control of the polymer characteristics, catalytic routes offer the broadest opportunity for the tailored synthesis of polyaminoboranes.

Scheme 1. (A) Amine–Borane Dehydropolymerization, (B) Exemplar Pre-Catalyst Systems.



A wide range of pre-catalyst systems have been described for amine-borane dehydropolymerization (Scheme 1B). After the original report of high[3] molecular weight polymer formed using $Ir(POCOP)H_2$ **A** [POCOP = κ^3-1,3-(^{t}Bu$_2$PO)$_2$C$_6$H$_3$],[1,11] systems based on group-4 metallocenes **B**,[18,19] cooperative ligands **C**,[14,16,20,21] and cationic $[RhL_2]^+$ pre-catalysts (L_2 = e.g., $Ph_2P(CH_2)_3PPh_2$, DPEphos, Xantphos) **D**,[22-24] have been described. For the Rh-based catalysts we have reported speciation, kinetics and degree of polymerization studies. These are broadly generalized by: an induction period, a non-living chain-growth propagation, an inverse relationship between catalyst loading and degree of polymerization, and H_2 acting as a chain controlling agent to reduce polymer chain length,[15,22-24] Scheme 2. We have also reported on the key role of $NMeH_2$, formed by B–N bond cleavage in $H_3B{\cdot}NMeH_2$.[21,25] Exemplified using the $[Rh(DPEphos)(H_2BNMe_3CH_2CH_2{}^tBu)][BAr^F{}_4]$ pre-catalyst,[23] **1** [Ar^F = 3,5-(CF$_3$)$_2$C$_6$H$_3$], the amine $NMeH_2$ removes the induction period, increases the degree of polymerization, and simplifies the kinetics, allowing a half order dependency on $[Rh]_{TOTAL}$ to be determined. However, the structure of the active catalyst is undetermined, with insight limited to the detection of a single species at $\delta(^{31}P)$ 41.3 [J(RhP) = 150 Hz]. Also lacking is a robust explanation for the relationship between $[Rh]_{TOTAL}$, and

Scheme 2: Exemplar Complex 1 and Prior Observations.

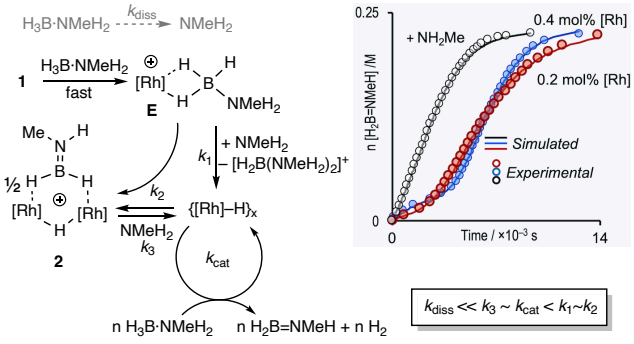


H_2, on the degree of polymerization.

Despite these advances, the precise details of initiation, propagation and termination remain to be determined for these diverse catalyst systems,[3] while identification of resting states is rare[14,16] and challenging.[18] Herein we report on an investigation of the [Rh(DPEphos)]$^+$ pre-catalyst system, **1**, in which a study of the kinetics, speciation and synthesis has allowed identification of the active catalyst, as well as the polymer-growth/termination processes to be interrogated. These insights are then harnessed in the design of a new, efficient, Rh-based catalyst that produces polyaminoborane on scale. A simple protocol is also described to significantly reduce the levels of residual catalyst in the isolated polymer.

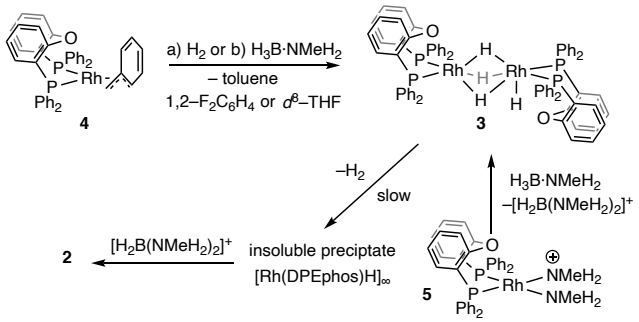
We have previously reported that when **1** is employed as pre-catalyst, the monocationic hydrido-aminoborane dimer [Rh_2(DPEphos)$_2$(μ-H)(μ-H_2B=NHMe)][BAr^F_4] **2** is formed during the early stages of reaction.[23] We propose this arises via an amine-promoted B–H hydride transfer[26] in a precursor cationic σ-amine borane complex [Rh(DPEphos)(H_3B·$NMeH_2$)][BAr^F_4], **E**,[27] to generate a neutral hydride of empirical formula Rh(DPEphos)H (Scheme 3). Similar hydride species are formed in [Rh(PONOP)(H_3B·NMe_2H)]$^+$ [25] and [Rh(^{i}Pr$_2$P(CH$_2$)$_3$P^{i}Pr$_2$)-(H_3B·NH_3)]$^+$ [28] systems, alongside H_2B=NMe_2/[NMe_2H_2]$^+$ or boronium [H_2B(NH_3)$_2$]$^+$ respectively. Based on these observations, a simple kinetics model was constructed for the induction process, involving generation of **2** by rapid trapping of Rh(DPEphos)H with unreacted **E**, followed by a slow, amine-dependent, fragmentation to form the active catalyst. This telescopes the elementary steps of the induction process,[29] allows H_2 evolution to be used as proxy for transient H_2B=NMeH, and successfully reproduces the temporal concentration profiles,[23] as a function of $[Rh]_{TOTAL}$ (0.2 and 0.4 mol%), or when $NMeH_2$ is added; Scheme 3. A VTNA analysis[30,31] supports the observation of an empirical fractional order in pre-catalyst: $[Rh]_{TOTAL}^{0.5}$.

Scheme 3. Model and Fitted data.[23] [BAr^F_4]$^-$, DPEphos Not Shown. [H_3B·$NMeH_2$] = 0.223 M (1,2–$F_2C_6H_4$).



With an effective model for the induction process determined, we then focussed on identification of the catalyst resting state. Based on our model, and the work of Fryzuk[32,33] and Tilley,[34] the neutral hydride bridged dimer [Rh(DPEphos)H_2]$_2$, **3**, was synthesized in situ, by addition of either H_2 or H_3B·$NMeH_2$ to the new benzyl complex Rh(κ^2–P,P–DPEphos)(η^3-H_2CPh) **4**, Scheme 4. Toluene is formed in all cases. The 298K ^{31}P{^{1}H} NMR data for **3** match that observed during catalysis, i.e. δ 41.3 [*J*(RhP) = 150 Hz, d^8–THF]. The hydride ligands in **3** are fluxional at 298 K, presenting a very broad signal at δ –8.1. Cooling to 253 K reveals three environments at δ –6.9 (2H), –9.9 (1H) and –17.5 (1H). This pattern is similar to those reported for $Rh_2L_4H_4$ [L = P(O^{i}Pr)$_3$, ½ ^{i}Pr$_2$P(CH$_2$)$_3$P^{i}Pr$_2$],[32,35] and is indicative of three bridging hydrides and one terminal hydride. The ^{31}P{^{1}H} NMR spectrum of **3** at 253 K was poorly resolved, showing multiple, mutually-coupled, signals.

Scheme 4. Synthesis and Reactivity of Complex 3. [BAr^F_4]$^-$ Not Shown.



Addition of excess H_3B·$NMeH_2$ to the amine complex [Rh(DPEphos)($NMeH_2$)$_2$][BAr^F_4], **5**,[23] also generates **3**, together with boronium [H_2B($NMeH_2$)$_2$]$^+$ [δ(^{11}B) –7.8]. Solutions of complex **3** in 1,2–$F_2C_6H_4$, or in THF, irreversibly lose H_2 on degassing, to form an insoluble yellow/brown powder, analyzing as [Rh(DPEphos)H]$_\infty$, likely to be a coordination polymer with Rh–H–Rh linkages. While the Rh-polymer does not dissolve on addition of H_2, the soluble complex **2** is regenerated when [H_2B($NMeH_2$)(OEt_2)][BAr^F_4] is added.[10] Thus, when using a cationic pre-catalyst (i.e. **1** or **5**), persistent $NMeH_2$ will favor soluble neutral hydride via equilibration with complex **2** (k_3, Scheme 3). When using neutral pre-catalyst **4**, a high initial concentration of amine-borane, e.g. [H_3B·$NMeH_2$]$_0$ = 0.446 M in THF, inhibits the formation of a precipitate. Presumably, the amine-borane intercepts Rh(DPEphos)H before it oligomerizes. Thus, dimeric, neutral, hydride **3** is observed as the common resting state, irrespective of the pre-catalyst, or solvent. The half order dependence in $[Rh]_{TOTAL}$ points to a rapid endergonic equilibrium between dimer and monomer, prior to the turn-over limiting step. This has been noted in other Rh_2H_x systems,[32,36,37] and the data are thus consistent with the resting state being dimeric **3**. An important difference between neutral versus cationic pre-catalysts, is that the latter generate a boronium co-product, which has important implications for the dehydropolymerization, as discussed next.

Neutral pre-catalyst **4** was deployed in the dehydropolymerization of H_3B·$NMeH_2$ at a variety of catalyst loadings, Table 1. In 1,2–$F_2C_6H_4$ as solvent, kinetics measurements were hampered by formation of the insoluble precipitate. In THF, the eudiometric measurements on H_2 production were less reliable due to solvent volatility. Nevertheless, polymerization goes to completion in both solvents, selectively forming [H_2BNMeH]$_n$, Figure 1A.[38] A plot of conversion versus M_n (Figure 1B, relative to polystyrene standards)[3,11,16] is characteristic of a non-living chain-growth polymerization: at low conversions the polymer is formed with high M_n and H_3B·$NMeH_2$ dominates. Variations in catalyst loading did not affect the degree of polymerization of the resulting polyaminoborane, in either 1,2–$F_2C_6H_4$ (Figure 1C, M_n = 15000 g mol^{-1}) or THF solutions (M_n = 17000 g mol^{-1}), under 'open conditions' with a slow Ar-flow. This is different to cationic pre-catalysts, such as **1**, where M_n scales inversely with $[Rh]_{TOTAL}$: e.g. 6400 (1 mol%), 34900 g mol^{-1} (0.2 mol%).[23] However, 'closed conditions' that allow for build–up of H_2 result in very low molecular weight oligomers being

Table 1 GPC Characterization Data[a]

Entry	Cat.	[Rh]$_{TOTAL}$ (mol%)	M_n [M_p] (g mol^{-1})[b]	Đ	[boronium] (mol%)

[a] 298 K, 1,2–$F_2C_6H_4$, 0.223 M $H_3B{\cdot}NMeH_2$, isobaric conditions under flow of Ar, end point determined by ^{11}B NMR spectroscopy. [b] Relative to polystyrene standards; triple column; RI detection; THF with 0.1 w/w % [NBu$_4$]Br; 35 °C; [sample] = 2 mg cm^{-3}. [c] THF solvent. [d] M_p of the polymer distribution obscured by $[BAr^F{}_4]^-$ signal. [e] 5 M, 1.1 g scale.

formed (1 mol % **4**, less than 1000 gmol^{-1} by GPC, ^{11}B NMR spectroscopy[31]); The cationic pre-catalyst **1** behaves analogously.[22]

The neutral and cationic pre-catalyst systems differ by the presence of a boronium co-product with the latter, the relative concentration of which will scale with [Rh]$_{TOTAL}$.[39] Given the underlying insensitivity to the degree of polymerization to [Rh]$_{TOTAL}$ when using neutral **4**, we thus considered whether with cationic pre-catalysts boronium $[H_2B(NMeH_2)_2][BAr^F{}_4]$ can act as a chain-control agent to modify M_n. To test this, $[H_2B(NMeH_2)_2][BAr^F{}_4]$ was doped (0.25 to 1 mol%) into 1 mol% **4** / $H_3B{\cdot}NMeH_2$, to selectively form polyaminoborane (^{11}B NMR). Although GPC analysis of the resulting polymer using refractive index detection is affected by the co-eluting $[BAr^F{}_4]^-$ masking the lower molecular weight region (Figure 1D),[15] there is a qualitative trend of decreasing M_p with increasing $[H_2B(NMeH_2)_2][BAr^F{}_4]$, Table 1. This outcome is consistent with boronium acting as a chain-control agent. Chain Length Distribution (ln–CLD) analysis of high molecular weight fractions in GPC has been shown to be useful where there is overlap between distributions of polymer and transfer agents, such as that noted here, allowing for chain control processes to be probed.[40] A Mayo-type plot of [boronium]/[$H_3B{\cdot}NMeH_2$] versus the ln–CLD slope indicates an inversely linear relationship (Figure 1E and F), further supporting the conclusion that the boronium functions as a rapid chain control agent in the dehydropolymerization.

Collectively, the analysis above facilitates the construction of a mechanistic landscape for dehydropolymerization, Scheme 5, that is consistent not only with the results herein, but also with our previous observations on cationic Rh-based systems.[15,22,23,28,41] Thus, dehydrogenation of amine-borane to give the reactive monomer, $H_2B{=}NMeH$, occurs at a neutral [Rh–H] species, in an H_2-mediated equilibrium with dimer **3**. Dehydrogenation to form $H_2B{=}NMeH$, via BH/NH activation (Scheme 5A) could be facilitated by a hemilabile DPEphos ligand (e.g. κ^2 and κ^3 coordination[42]) as previously suggested.[43]

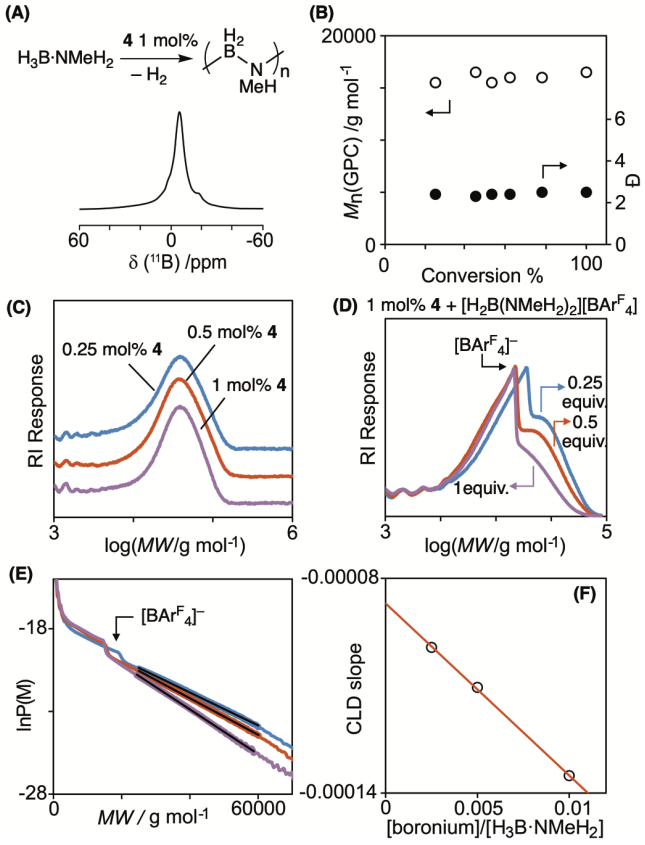

Figure 1. Polyaminoborane data obtained using catalyst 4 (Ar flow, 1,2–$F_2C_6H_4$, $H_3B{\cdot}NMeH_2$ = 0.223 M) (A) ^{11}B NMR spectrum of polymer; (B) M_n versus conversion; (C) GPC data for 1.0, 0.5 and 0.25 mol% catalyst loadings; (D) GPC data for 1.0 mol% 4 with $[H_2B(NMeH_2)_2][BAr^F{}_4]$ doping. (E) ln–CLD plot of high M_w fraction (D). (F) Mayo analysis.

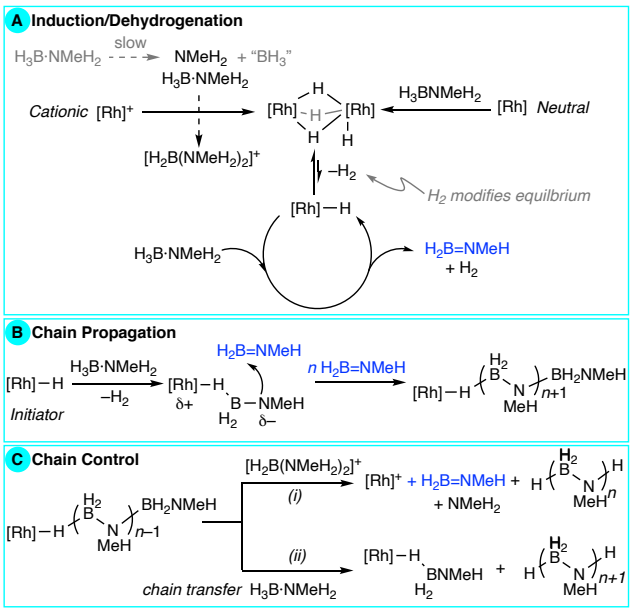
Scheme 5. Proposed (A) Catalyst Evolution/Dehydrogenation, (B) Propagation, (C) Chain–Control Events.



Initiated by a formal hydride-transfer from the rhodium hydride,[44] that is now playing a dual role in both dehydrogenation and initiation,[11,14] H_2B=NMeH then undergoes rapid head-to-tail end-chain nucleophilic B–N bond formation, as proposed previously (Scheme 5B).[12,13,15, 16] Chain-control by protonation of the terminus nucleophilic amine of the polymeryl group by boronium returns a cationic pre-catalyst, aminoborane and $NMeH_2$, that are rapidly recycled (Scheme 5C).[25] A related intramolecular proton transfer has been proposed by Paul and co-workers for Ir(POCOP)H_2 systems.[13] We speculate that, in the absence of boronium, chain transfer to pre-monomer $H_3B{\cdot}NMeH_2$ controls chain-length, Scheme 5C. Whatever the precise mechanism for these chain-control processes, they result in relatively narrow dispersities of the final isolated polymer, and constant degrees of polymerization during propagation (Figure 1B).[45] H_2 loss from **3**, and related systems,[32,35] occurs readily on degassing. The position of the initial monomer/dimer equilibrium is thus expected to be sensitive to [H_2], impacting on the rate of dehydrogenation as well initiator concentration. This, we suggest, is the origin of the low degrees of polymerization observed under 'closed conditions'. In support of this, for a system where hydride-bridged dimer formation is disfavoured due to sterics, Rh(Xantphos-^{i}Pr)H, H_2 does not act to modify the degree of polymerization.[15] The precise gearing of all of these interconnected relationships is therefore pre-catalyst, co-product (e.g. boronium) and solvent specific.

The use of new pre-catalysts based upon neutral **4** demonstrates wider applicability (Figure 2, Table 1). For example, the Xantphos benzyl complex, **6**, is an effective pre-catalyst for dehydropolymerization (1 mol%, 88000 g mol^{-1}, $Đ$ 1.6), and the degree of polymerization can be controlled by [$H_2B(NMeH_2)_2$][$BAr^F{}_4$], e.g. 1 mol% M_n = 21000 g mol^{-1}. Complex **6** can be used at low loadings and high [$H_3B{\cdot}NMeH_2$] (0.1 mol%, 5 M in THF, using commercially sourced amine-borane), to produce high[3] molecular weight polyaminoborane on gram scale (85000 g mol^{-1}, 1.1 g). Use of activated charcoal in the polymer work-up reduces the [Rh]-content from 195 ppm (no workup) to 81 ppm. This is considerably lower than reported for other Rh and Co dehydropolymerization systems.[15,21,46] The simple benzyl-dppp-catalyst **7** also promotes formation of high molecular weight polyaminoborane (98000 g mol^{-1}).

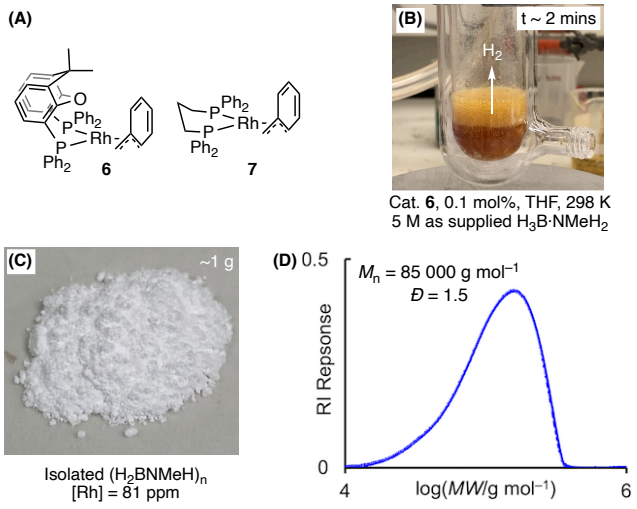


Figure 2. (A) New pre-catalysts, (B) Representative reaction, (C) Isolated polymer and (D) GPC trace [cat. = 5, 0.1 mol%].

In summary, the identification of the catalyst resting state, the events that lead to its formation, and thus the role that co-products such as boronium and H_2 likely play in chain-control, have provided important insights into the complex and nuanced set of interconnected processes that are required for selective amine-borane dehydropolymerization using Rh(bisphosphine)-based catalysts. While the detailed elucidation of the elementary steps awaits further study, Scheme 5 provides a testable framework for the analysis and design of catalyst systems for controlled amine-borane dehydropolymerization.
